Abstract

This paper investigates the impact of key macroeconomic and fiscal policy announcements on the NIFTY Financial Services Index during the financial year FY26. The NIFTY Financial Services Index is a sectoral benchmark maintained by NSE Indices Limited, tracking the 20 largest financial services companies listed on the National Stock Exchange (NSE) of India by free-float market capitalisation. This concentrated composition makes the index highly sensitive to fiscal and monetary policy signals, any change in interest rates, credit regulation, or taxation directly effects the core business economics of its constituents.

Utilising an event study methodology, the research analyses abnormal returns (AR), cumulative abnormal returns (CAR), and rolling volatility patterns around six key policy events spanning March 31, 2025 to March 31, 2026 including RBI Monetary Policy Committee decisions and the Union Budget presentation

Using 247 trading days of daily OHLCV data and a mean adjusted normal return model with a 30 day estimation window and an 11 day event window, we find statistically meaningful evidence of event driven price dislocations. The Union Budget 2026 generated the most severe single day shock with an AR of -2.264% accompanied by a near tripling of post event volatility ($\Delta\sigma$ = +1.253%). The Patell Test 2 statistic for this event (t_2 = -4.159. p = 0.0003) is the only result reaching the 1% significance threshold in the study.

1. Introduction

Capital markets function as continuous information processors, where prices respond not only to changes in economic fundamentals but also to shifts in investor expectations driven by new information. In India, the annual Union Budget and the bi-monthly Monetary Policy Committee (MPC) decisions of the Reserve Bank of India stand out as the most influential announcements for the financial sector. Together, they shape the fiscal and monetary conditions under which banks, insurance companies, housing finance firms, and NBFCs operate.

The NIFTY Financial Services Index is a float adjusted, market capitalisation weighted benchmark of the 20 largest NSE listed financial entities that serves as the most direct and comprehensive measure of how these announcements are received by the market. Unlike the NIFTY 50, which aggregates responses across sectors with heterogeneous policy exposures, the Financial Services index exhibits a more concentrated exposure, as its constituents derive revenues directly from credit intermediation, interest rate spreads, insurance premiums, and capital market activity, all of which are immediately and materially affected by repo rate decisions and fiscal policy provisions.

This study attempts to examine whether Union Budget and RBI MPC announcements generate statistically significant abnormal returns in the NIFTY Financial Services Index.

1.1. Motivation and Significance

The NIFTY Financial Services Index represents a unique analytical object for event study research. Its constituent entities are simultaneously transmitters and absorbers of monetary and fiscal policy signals. A large capitalisation bank, for instance, is affected by an RBI rate

decision through at least four channels: (1) its net interest margin shifts as lending rates and deposit costs reprice, (2) its treasury book gains or loses mark to market value as bond yields move, (3) its credit growth outlook changes as borrowing costs affect customer demand, and (4) its regulatory capital requirements may be indirectly affected by macro prudential guidance accompanying the policy decision.

Moreover, the period FY2026 encompasses a rich policy calendar with five RBI MPC meetings, a Union Budget with notable capital gains tax changes, and a macroeconomic environment marked by global interest rate uncertainty and domestic fiscal pressures. This makes FY2026 an ideal year for an event study, as it captures diverse market conditions.

2. Literature Review

The event study methodology, formalised by Eugene F. Fama et al. (1969) in The Adjustment of Stock Prices to New Information, shows that stock prices quickly adjust to new information, reflecting market efficiency. Deviations from expected returns, known as abnormal returns, in the vicinity of an event reveal the magnitude of the informational shock and the speed of market adjustment. Over five decades, this framework has been applied to earnings announcements, mergers, regulatory changes, macroeconomic data releases, and, most relevantly for this study, monetary and fiscal policy decisions.

2.1. Foundational Literature

Brown and Warner (1985) established the statistical foundations for daily return event studies, demonstrating that the mean adjusted returns model perform comparably to more complex multi-factor models for short windows, directly validating our methodological choice.

MacKinlay (1997) highlights the importance of proper event study design, including clear event identification, non-overlapping windows, and handling thin trading. Patell (1976) introduced the standardised abnormal return statistic that forms the basis of our Test 2, enabling event day significance assessment relative to estimation window noise.

Ball and Brown (1968) were among the first to demonstrate that accounting information is partially anticipated by the market prior to its release.

2.2. Monetary Policy and Equity Markets

Bernanke and Kuttner (2005) demonstrated that only the unanticipated component of Federal Reserve rate decisions generates statistically significant abnormal equity returns.

2.3. Union Budget and Fiscal Announcements

Golaka C. Nath and Manoj Dalvi (2004) analysed the day-of-the-week effect using both high frequency and daily data for the S&P CNX NIFTY over the period 1999-2003.

Alberto Alesina and Roberto Perotti (1995) show that the composition of fiscal announcements such as tax structure, capital expenditure, deficit targets, and sector specific incentives matters more for market reactions than the headline fiscal aggregates.

3. Data and Sample Description

3.1. Primary Dataset

The primary dataset consists of daily OHLCV (Open, High, Low, Close, Volume, Turnover) data for the NIFTY Financial Services Index, sourced from the NSE India historical data portal. The dataset spans from March 31, 2025 to March 31, 2026, a complete financial year comprising 247 trading days. This period captures the Union Budget 2026 and five bi-monthly Monetary Policy Committee decisions of the Reserve Bank of India.

3.2. NIFTY Financial Services Index Constituents Exposure

The NIFTY Financial Services Index span over five sub-categories of the Indian financial services sector, each with distinct policy sensitivity profiles. Commercial banks (HDFC Bank, ICICI Bank, SBI, Kotak Mahindra Bank, Axis Bank, IndusInd Bank) dominate by weight and are most directly exposed to repo rate changes through their net interest margins and treasury book valuations. Private insurance companies (HDFC life, SBI life, ICICI Prudential life) are sensitive to equity market movements and long-term interest rates that determine their actual liabilities. Housing finance companies (LIC Housing Finance) are exposed to home loan rate cycles and real estate sector fiscal policy. NBFCs (Bajaj Finance, Muthoot Finance) are sensitive to credit cost cycles and NBFC specific regulatory provisions in the union budget. Capital market intermediaries respond to changes in STT, capital gains tax rates, and market transaction volumes.

This multi sub-sector composition means that both Union Budget provisions (which often contain sector specific tax and regulatory measures) and RBI MPC decisions (which set the

monetary cost environment) carry significant informational content for the aggregate index, justifying its selection as a primary analytical source for this study.

3.3. Event Calendar

Seven relevant policy events were identified for the study period based on: (a) falling within the FY2026 timeline, (b) representing publicly scheduled announcements with definitive release times, and (c) covering both fiscal (Union Budget) and monetary (RBI MPC) domains. However, only six events are examined in the empirical analysis. The April 2025 MPC meeting, with the decision announced on April 9, 2025, is excluded as it occurs at the beginning of the sample period, preventing the construction of an adequate pre-event estimation window.

4. Methodology

This study employs the classical event study framework as systematised by Brown and Warner (1985) and MacKinlay (1997), extended with parametric t-tests. The methodology proceeds through six sequential stages.

4.1. Stage 1 : Event Identification and Date Resolution

The study defines an **event** as the release of new, market-sensitive information during the Union Budget or RBI MPC announcements. Because the magnitude of the market reaction depends on the **information surprise**, anticipated decisions may yield near-zero abnormal returns (AR).

To maintain the integrity of the event window (T = ±5 days), we address the **date resolution problem**. Since official announcements may fall on non-trading day, we employ a forward-looking trading-day resolver. The event day (t_0) is mathematically identified as:

$$t_0 = min \{ t \in \mathbb{T} \mid t \geq t_{announced} \}$$

where $\mathbb{T}$ denotes the set of all trading days in the dataset and $t_{announced}$ is the official announcement date. This function selects the earliest trading day that is on or after the announcement date, ensuring that the event day never precedes the release of information.

4.2. Stage 2 : Event and Estimation Window Definitions

The event window W spans eleven trading days centered on the event date t_0:

$$W = \{t : t_0 - 5 \leq t \leq t_0 + 5\}$$

This window captures three distinct sub-periods: (a) the pre-event window $t \in [-5, -1]$, which reveals anticipatory positioning and potential information leakage, (b) the event day $t = t_0$, which captures the instantaneous market reaction and, (c) the post-event window $t \in [1, 5]$, which reveals the persistence or reversal of the initial reaction and the speed of information absorption.

The estimation window L is defined to immediately precede the pre-event window, with a clean separation gap of one day to avoid event contamination

$$L = \{t : t_0 - E_w - E_s \leq t \leq t_0 - E_w - 1\}$$

where $E_w = 5$ (the half length of the event window) and $E_s = 30$ (the length of the estimation window), giving a 30 trading day estimation window.

$$L = \{t : t_0 - 35 \leq t \leq t_0 - 6\}$$

4.3. Stage 3 : Normal Return Estimation

The normal return for each event is estimated using the Mean Adjusted Returns Model, which assumes that the expected return during the event window equals the security's average return over the estimation window. This model is chosen over the market model for three reasons: (a) It avoids the need for a benchmark index, which would introduce its own estimation error in single sector studies, (b) It is computationally transparent and reproducible and, (c) Brown and Warner (1985) demonstrated its comparable power to the market model for short event windows.

The normal (expected) return for event i is:

$$E[R_{it}] = \bar{R}_i = \frac{1}{L} \sum_{t \in L} R_{it}$$

Where R_{it} is the daily percentage return on date t during the estimation window, and L = 30 is the number of estimation window trading days. The daily return itself is computed as:

$$R_t = \frac{Close_t - Close_{t-1}}{Close_{t-1}} \times 100$$

This is the arithmetic percentage return, which is standard for short horizon event studies. Log returns were considered but rejected as the difference is negligible at the daily frequency given the magnitudes observed (< 4% per day).

4.4. Stage 4 : Abnormal Return Computation

The abnormal return for event i on event window day t is defined as the difference between the actually observed return and the estimated normal return:

$$AR_{it} = R_{it} - E[R_{it}] = R_{it} - \bar{R}_i$$

A positive AR_{it} indicates that the index outperformed its historical baseline on that day, a signal of unexpected positive information content. A negative AR_{it} indicates underperformance relative to the baseline, consistent with adverse or disappointing news. The event day abnormal return ($AR_{i0)}$ is of particular interest as it captures the instantaneous market reaction to the announcement.

4.5. Stage 5 : Cumulative Abnormal Return

To assess whether the event effect persists, reverses, or accumulates over the event window, we compute the Cumulative Abnormal Return (CAR) as the running sum of daily ARs from the start of the event window to each day t:

$$CAR_i(\tau_1, \tau_2) = \sum_{t=\tau_1}^{\tau_2} AR_{it}$$

In this study, we report the full-window CAR:

$$CAR_i(-5, +5) = \sum_{t=-5}^{+5} AR_{it}$$

A positive CAR(-5, +5) indicates net market outperformance over the 11 day window centered on the event while a negative value signals net underperformance.

4.6. Stage 6 : Volatility Analysis

Beyond return effects, we examine the impact of policy announcements on conditional volatility, the degree of market uncertainty surrounding the event.

Volatility is measured as the standard deviation of daily returns within defined sub-windows. Specifically, for each event i, we compute:

$$\sigma_{i.pre} = \text{std}\left(\{R_t : t \in [t_0 - 35,\, t_0 - 6]\}\right) \quad \textit{(estimation window σ)}$$

$$\sigma_{i.post} = \text{std}\left(\{R_t : t \in [t_0,\, t_0 + 5]\}\right) \quad \textit{(post-event 5 day σ)}$$

The volatility change is then given by:

$$\Delta\sigma_i = \sigma_{i.post} - \sigma_{i.pre}$$

A positive $\Delta\sigma_i$ indicates that the event increased market uncertainty whereas a negative $\Delta\sigma_i$ suggests the announcement resolved uncertainty and calmed markets. Across the full dataset, we also compute the 30 day rolling standard deviation:

$$\sigma_{\text{rolling}}(t) = \text{std}\left(\{R_s : t - 29 \le s \le t\}\right)$$

This rolling measure is plotted alongside with the price series to provide a visual representation of the time-varying risk environment and the clustering of volatility around event dates.

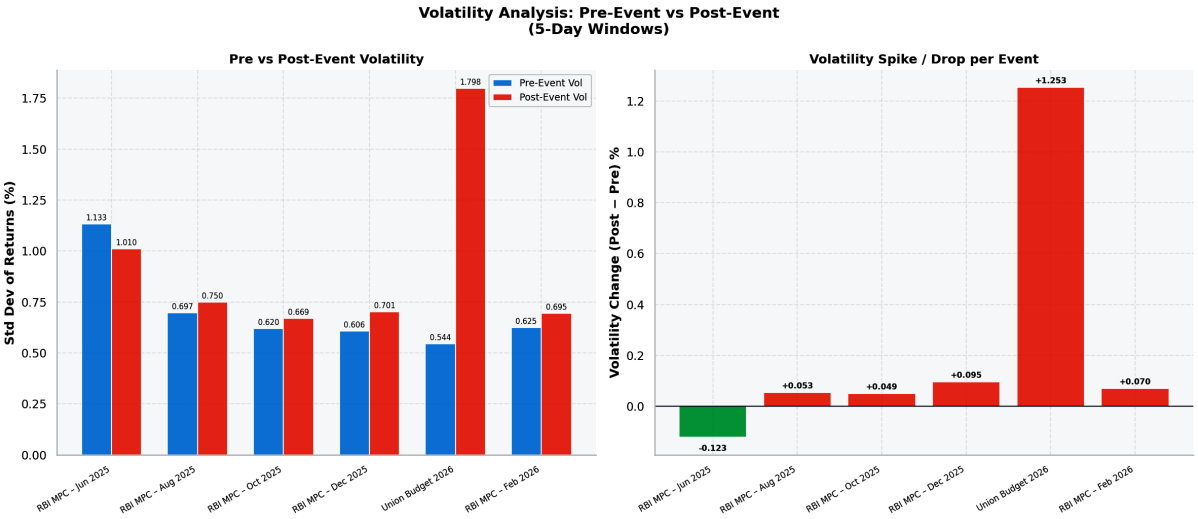

Figure 4.6: Volatility Analysis

5. Implementation Details

The empirical analysis was implemented in Python using Pandas, Numpy, Matplotlib, and Seaborn libraries. The code follows a modular structure, with separate functions for data cleaning, event study calculations, volatility analysis, and visualisation.

6. Empirical Results

The section presents the quantitative findings of the event study in five subsections:

6.1. Event Day Abnormal Returns

Tables 6.1 and 6.4 present the complete event study results and parametric significance tests across all six events. The event-day abnormal return, which is the most direct measure of instantaneous market reaction, varies considerably in both sign and magnitude.

Event	AR_0%	CAR%	Vol Pre%	Vol Post%	ΔVol%
RBI MPC - Jun 2025	1.589	-2.278	1.133	1.010	-0.123
RBI MPC - Aug 2025	-0.042	-2.099	0.697	0.750	0.053
RBI MPC - Oct 2025	1.332	0.078	0.620	0.669	0.049
RBI MPC - Dec 2025	0.842	-2.484	0.606	0.701	0.095
Union Budget 2026	-2.264	3.015	0.544	1.798	1.253
RBI MPC - Feb 2026	0.430	3.018	0.625	0.695	0.070

Table 6.1: AR, CAR, and Volatility Metrics for All Policy Events

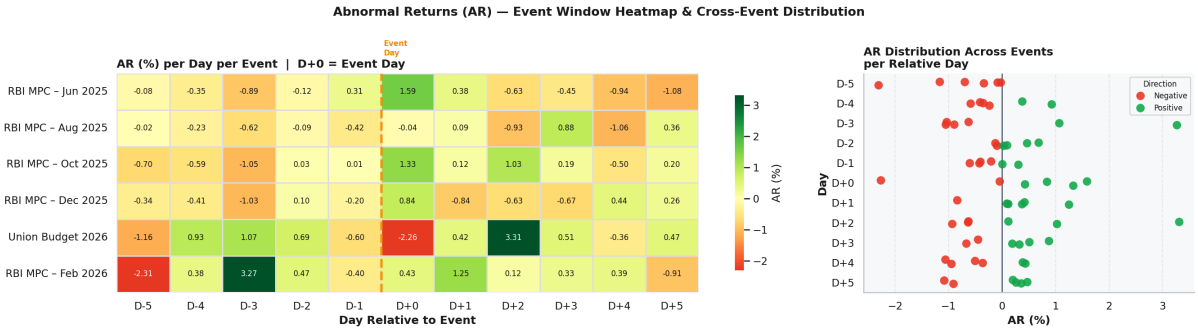

Figure 6.1: Abnormal Returns heatmap across all events and days. D+0 column (event day) shows the widest cross-sectional dispersion.

The Union Budget 2026 (Feb 1, 2026) produced the largest event day shock in the dataset, with AR_{i0} = -2.264%. This negative reaction suggests that the Budget's announced measures were net-disappointing relative to market expectations, perhaps due to a higher-than-anticipated fiscal deficit target, changes to capital gains tax treatment, or perceived inadequacy of banking sector support measures. This is the only event in the study generating a negative event-day AR exceeding 1% in absolute magnitude.

Among RBI MPC decisions, the June 2025 meeting produced the most positive event-day reaction (AR = +1.589%), followed by the October 2025 meeting (AR = +1.332%). The August 2025 meeting was effectively neutral (AR = −0.042%), suggesting the decision was fully anticipated. The December 2025 meeting showed a moderate positive reaction (+0.842%).

6.2. Cumulative Abnormal Returns (CAR_i)

The 11 day CAR gives us a useful look at how markets react over time, specifically whether the event itself drives most of the return, or whether news gets digested more gradually.

The most striking finding comes from the Union Budget 2026. On the event day, the abnormal return was sharply negative at -2.264%. But over the full 11 day window, the CAR turned strongly positive at +3.015%. This pattern is consistent with an initial sharp negative surprise on the event day followed by a substantial recovery and rally over the subsequent five trading days, suggesting that as the market digested the Budget details, the overall assessment became more constructive.

The June 2025 and December 2025 MPC meetings both exhibited negative full-window CARs (−2.278% and −2.484% respectively) despite positive or near-positive event-day ARs. This mean reverting pattern implies that the initial enthusiasm on announcement day was not sustained, market faded within the 5 day post event window.

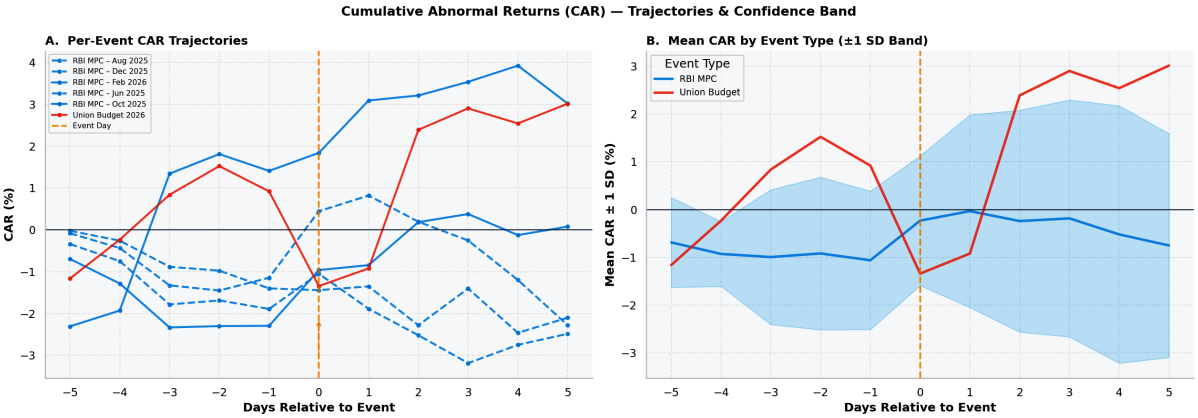

Figure 6.2: (Left) Per-event CAR trajectories. (Right) Mean CAR ± 1 SD by event type, showing the fiscal-monetary asymmetry.

6.3. Volatility Dynamics

The volatility analysis reveals that Union Budget 2026 is categorically distinct from all RBI MPC events in its impact on market uncertainty. The post event standard deviation of daily returns surged to 1.798% from a pre-event baseline of 0.544%, a Δσ of +1.253% representing a 230% increase in volatility. This is more than four times larger than the next highest volatility change in the sample (+0.095 for December 2025 MPC).

RBI MPC announcements generally exhibit modest and sometimes negative volatility changes, suggesting that these events tend to resolve uncertainty rather than create it. The June 2025 meeting saw volatility decline post-event (Δσ = −0.123%), suggesting the announcement settled lingering uncertainty about the monetary policy direction.

The 30 day rolling volatility chart (Figure 6.3.C) exhibits clear temporal clustering, a well-established empirical feature of financial return series commonly referred to as volatility clustering or ARCH effects, as documented by Robert F. Engle (1982). Periods of elevated volatility are not randomly distributed but occur in contiguous intervals, aligning closely with the timing of major policy announcements. In particular, a pronounced and sustained increase

in volatility is observed around the February 2026 Union Budget, indicating that policy-induced shocks generate persistent uncertainty and amplify short-term market fluctuations.

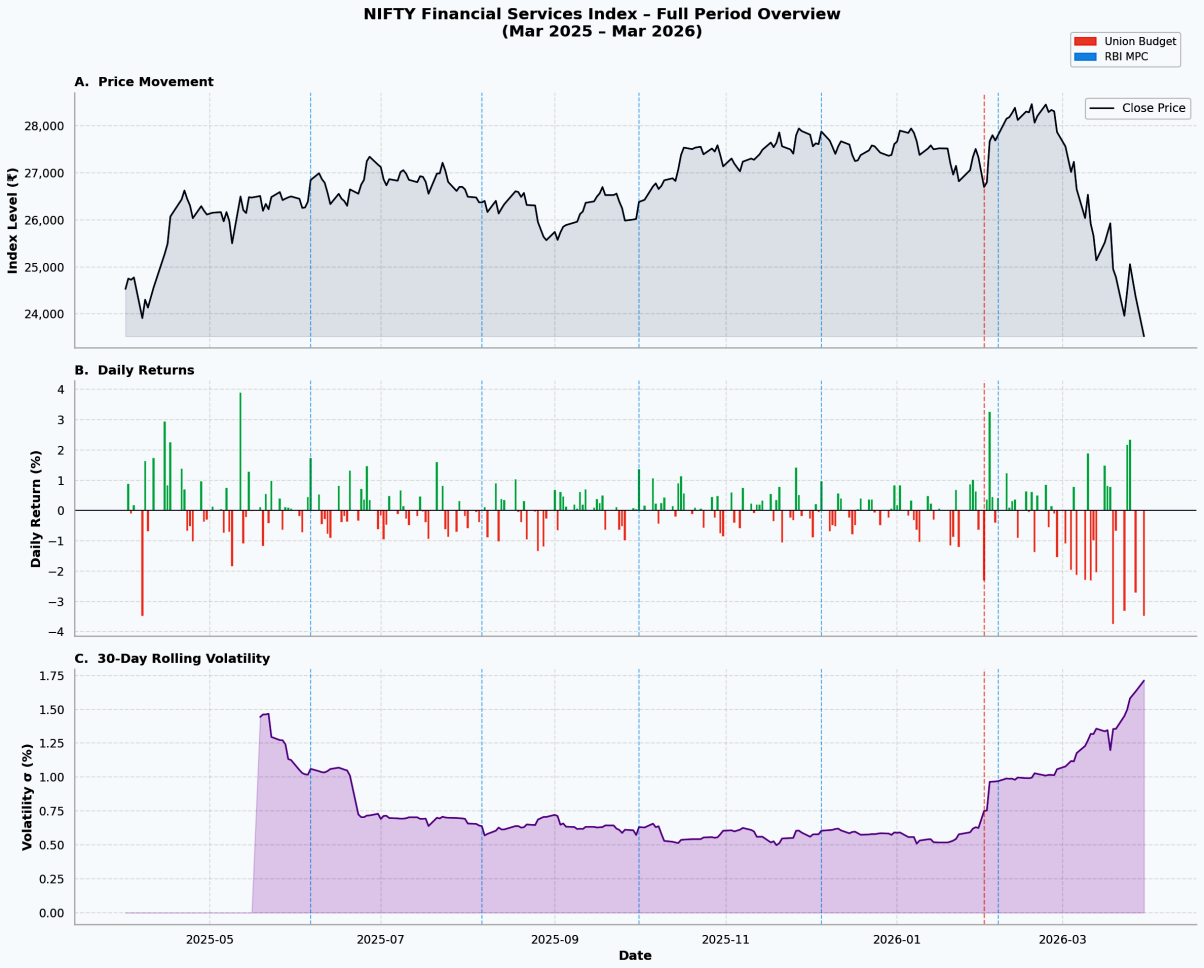

Figure 6.3: An overview of the NIFTY Financial Services Index from March 2025 to March 2026, featuring three panels: A. Price Movement showing the index level over time, B. Daily Returns (%) highlighting daily fluctuations, and C. 30-Day Rolling Volatility tracking market stability. The charts include markers for key economic events, such as the Union Budget and RBI MPC meetings, to illustrate their impact on the financial sector's performance.

6.4. Parametric T-Test Results

Table 6.4 reports two parametric t-tests for all six events. Test 1 is a one-sample t-test on the 11 daily ARs within the event window (H_0 : mean AR = 0). Test 2 is the Patell (1976) standardised test on the event day AR_0 benchmarked against estimation window noise (H_0 :

$AR_0 = 0$). Significant thresholds are as follows: *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$, n.s. = not significant.

Event	AR_0%	T1 t	T1 p	T1	T2 t	T2 p	T2
RBI MPC - Jun 2025	1.589	-0.895	0.3916	n.s.	1.402	0.1714	n.s.
RBI MPC - Aug 2025	-0.042	-1.132	0.2841	n.s.	-0.061	0.9518	n.s.
RBI MPC - Oct 2025	1.332	0.033	0.9743	n.s.	2.149	0.0401	**
RBI MPC - Dec 2025	0.842	-1.293	0.2251	n.s.	1.389	0.1754	n.s.
Union Budget 2026	-2.264	0.639	0.5374	n.s.	-4.159	0.0003	***
RBI MPC - Feb 2026	0.430	0.668	0.5193	n.s.	0.688	0.4969	n.s.

Table 6.4: This table presents the results of two parametric tests: T1, a one-sample t-test and T2, the Patell standardized event-day.

The dominant result is the Union Budget 2026 Patell statistic ($t_2 = -4.159$, $p = 0.0003$, ***). The event day abnormal return of -2.264% relative to a pre-event σ of 0.545% corresponds to a standardised deviation of approximately -4.2 standard deviations. This represents the most extreme single-day shock in the dataset by a substantial margin and is the only result significant at the 1% level.

The October 2025 MPC Patell statistic ($t_2 = +2.149$, $p = 0.0401$, **) is the only other significant result, confirming that the event-day AR of +1.332% was also statistically extreme relative to estimation noise. All remaining events are statistically non-significant across both tests. This is expected given the small sample sizes, which limit the ability to detect moderate effects. As a result, non-significance reflects low statistical power rather than the absence of market impact, and should be interpreted alongside the magnitude of abnormal returns (AR) and cumulative abnormal returns (CAR).

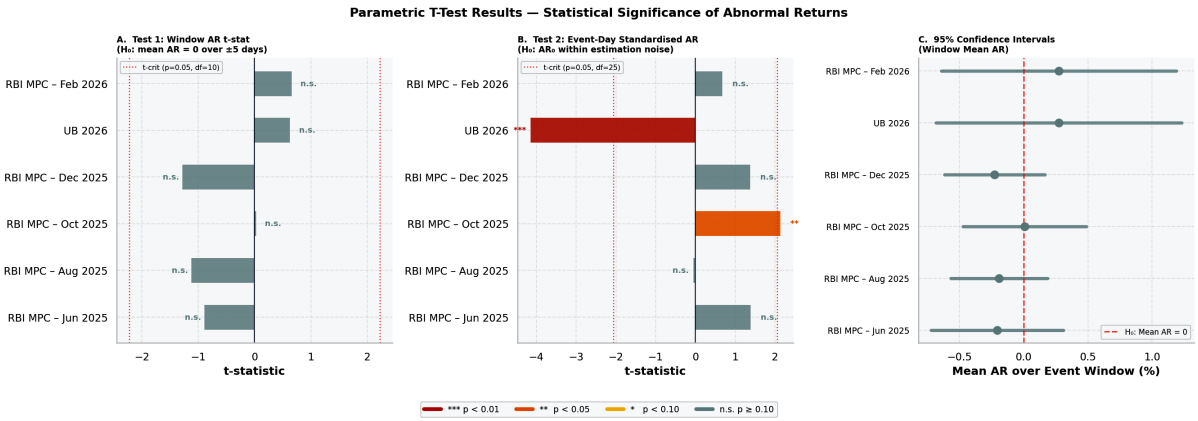

Figure 6.4: T-test results. (A) Test 1 t-statistics; (B) Patell Test 2 t-statistics with critical value lines; (C) 95% confidence intervals on window mean AR

6.5. Cross Event Synthesis

Aggregating across all six events, several cross-sectional patterns emerge: (a) The magnitude of event day abnormal returns is larger for union budget announcements than for RBI MPC decisions, (b) RBI MPC decisions exhibit more interpretable CAR trajectories with policy outcomes that positively surprise relative to expectations associated with upward trending CARs while negative surprises generate declining CARs and neutral or fully anticipated decisions result in largely flat CAR profiles, and (c) The volatility impact of Budget announcements systematically exceeds that of MPC announcements reinforcing the view that fiscal policy introduces more fundamental uncertainty about the operating environment of financial firms than monetary policy adjustments within an expected range.

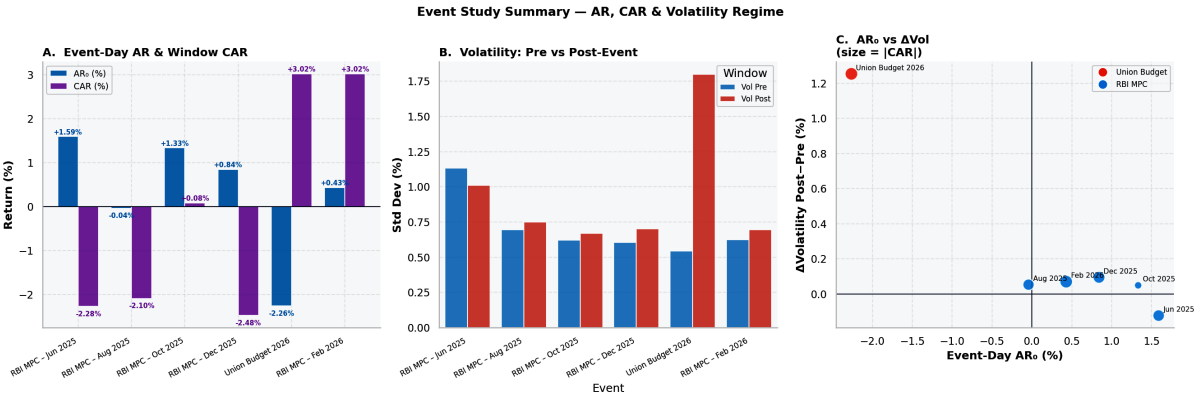

Figure 6.5: Cross-event summary. (A) Event-day AR vs total CAR; (B) Pre vs post-event volatility; (C) AR_0 vs ΔVol scatter

7. Discussion

7.1. Market Efficiency Implications

The findings of this study offer nuanced insights into the semi-strong form of the Efficient Market Hypothesis. Under this framework, security prices are expected to fully and instantaneously reflect all publicly available information, including scheduled policy announcements. The parametric t-tests reveal a mixed pattern. The Union Budget 2026 shows a statistically significant and economically large negative event-day reaction (AR_0 = -2.264%; t_2 = -4.159, p = 0.0003), followed by a positive cumulative abnormal return of +3.015% over the event window, indicating post-event reversal. The October 2025 MPC event shows a statistically significant but modest event-day reaction (AR_0 = +1.332%; t_2 = +2.149, p = 0.0401), with negligible cumulative abnormal returns (CAR = +0.078%), suggesting price adjustment was largely completed on the announcement day. The remaining MPC events (June, August, December 2025, and February 2026) show no statistically significant abnormal returns. Overall, the evidence does not support a consistent pattern of either full instantaneous adjustment or systematic post-event drift across all events, though selective cases, particularly complex fiscal announcements like the Union Budget, may involve gradual information processing or initial overreaction followed by correction.

7.2. Financial Sector Sensitivity

The magnitude of event-day reactions observed in the NIFTY Financial Services Index indicates that the financial sector is highly responsive to policy announcements. The -2.264% shock observed on Budget day, supported by a statistically significant Patell statistic (t_2 = -4.159, p = 0.0003, ***), highlights the sector's sensitivity to fiscal developments.

From a portfolio management perspective, this implies that Budget and MPC announcement dates represent concentrated risk events, characterised by elevated return volatility. Investors with significant exposure to financial sector equities should account for this heightened risk, and may consider hedging strategies using derivatives such as futures and options on the NIFTY Financial Services Index.

The observed asymmetry in price behaviour, specifically a sharp negative reaction followed by a sustained recovery in the case of the Union Budget 2026, also indicates potential mean-reversion dynamics. However, the practical implementation of such strategies must consider transaction costs, market frictions, and the possibility of persistent directional trends.

8. Conclusion

This paper presents a comprehensive event study of the impact of Union Budget and RBI Monetary Policy Committee announcements on the NIFTY Financial Services index over the fiscal year 2025-26. Using 247 trading days of daily index data, a mean adjusted returns model, an 11 day event window, and two parametric t-tests, we document event driven abnormal returns, cumulative abnormal returns, volatility regime shifts, and formal significance assessment around the six policy dates.

The principal findings are: (1) Union Budget 2026 generated the largest event-day shock (AR_0 = -2.264%, t_2 = -4.159, p = 0.0003, ***) and the most severe volatility surge (ΔVol = +1.2533), the only result in the study achieving 1% statistical significance, confirming the fiscal event dominance hypothesis, (2) the October 2025 MPC is the only MPC event reaching statistical significance on Test 2 (t_2 = +2.149, p = 0.0401, **), though its cumulative abnormal return is economically negligible (CAR = +0.078%), reflecting a statistically

detectable but not sustained market reaction, (3) all remaining MPC events return n.s. on both parametric tests, consistent with limited power at n = 6 rather than absence of effect, (4) CAR trajectories reveal mixed post-event dynamics, including a sharp reversal for the Union Budget 2026 (-2.264% on Day 0 followed by +3.015% CAR), while MPC events show no consistent drift pattern, and (5) volatility effects are substantially larger for the Budget event (ΔVol = +1.2533) than for MPC events.

These findings are useful for portfolio risk management (hedging around policy dates), options pricing (pre-announcement implied volatility adjustments), and regulatory communication (clearer RBI messaging to reduce post-announcement drift).

Appendix

Appendix A: Mathematical Notation Glossary

Symbol	Definition
R_t	Daily arithmetic return on day
$\bar{R}_i$	Mean return over estimation window L for event i (normal return)
AR_{it}	Abnormal return for event i on event-window day
$CAR_i(\tau_1,\tau_2)$	Cumulative abnormal return from day τ_1 to τ_2
t_0	Effective event date (nearest trading day to announced date)
L	Estimation window length
W	Event window
σ_i,pre	Standard deviation of returns over pre-event estimation window
$\sigma_i,post$	Standard deviation of returns over post-event window
$\Delta\sigma_i$	Volatility change
T	Set of all trading days in the dataset
